Powers of 5 of the form 2^k (i.e. $5^{(2^k)}$) can be computed quickly by successive squaring. For example,

$$5^{16} = (5^8)^2$$

$$5^8 = (5^4)^2$$

$$5^4 = (5^2)^2$$

$$5^2 = (5^1)^2$$

This should give you the modified algorithm almost immediately.

That's perfect. I wish I had thought of that. I rewrote the function in Python for the sake of being concise, but now the function takes k rather than 2^k as its argument. So I guess I haven't really answered the question.

```
def power(k):  
    if (k <= 1):  
        return 5  
    else:  
        return power(k-1)**2
```

<snip>

Also, I'm sort of curious what school is still using Pascal as an introductory language. Not that I'm complaining—I think Pascal could still be a righteous choice for an intro vehicle; I'd just like to know what school still has the stones to resist jumping on the C#/C++/C/Java bandwagons.

Re: Powers of 5

That would be Drexel University. The course I've been taking covers data structures and algorithms, and therefore the programming component is small. Courses with greater emphasis on programming have entered into a sordid love affair with OO languages, especially C++ and Java. At least, that's how it seems to an outsider. (My home institution is the University of Chicago. They started us with Scheme, which made me loathe the nested parentheses for a while.)

At any rate, I digress. I'm just missing how to get the function to take 2^k as its argument. If you don't mind helping a little more, I would be grateful.
