I wear a pacemaker, implanted three years ago against bradycardia, and have intermittent afib with 0 to 1 episodes monthly, lasting from a few hours to a couple of days.

Reading the printouts released upon my periodical pacemaker controls, I notice that the detected "mode changes" are a lot more than the detected "atrial high frequency episodes" (frequency indicated as "over 400").

Can you explain such apparent non-correlation between those two event categories?

One more question: I hearsay that a pacemaker cannot detect tachycardia events with frequency in the range of 100-110. Is that correct?
